## Abstract

We study how lightweight adapters trained on top of frozen vision-language encoders behave under distribution shift. We identify a structural in-distribution/out-of-distribution (ID/OOD) tradeoff among existing adapter training paradigms. Global contrastive objectives such as ICon and SRL, when paired with high-capacity adapters, achieve near-perfect in-distribution Label Precision on CIFAR-100 (0.999 and 0.992 at K=1, nprobe=1) but collapse to 0.562 and 0.552 on the unseen classes of Food-101, a 44 percentage point drop. Low-capacity alternatives such as LoRA avoid this collapse but underperform substantially in-distribution. We propose Euclidean Geodesic Alignment (EGA), a residual adapter trained with a small-margin triplet loss on the class-aware neighborhood graph of pre-trained embeddings. EGA converges to a sparse-gradient scheme in which 96.5 percent of training triplets produce zero gradient at steady state. This design preserves the pre-trained semantic structure for unseen categories while enabling high-capacity in-distribution refinement. Across CIFAR-100 (ID) and three OOD benchmarks (CIFAR-10, FGVC-Aircraft, Food-101), the six methods we evaluate trace out a Pareto frontier in the (ID, OOD) Label Precision plane. EGA occupies a distinct operating point on this frontier, offering the highest in-distribution Label Precision among adapters that avoid OOD collapse together with bounded OOD degradation. These benefits generalize to stronger backbones: on DINOv2-large and SigLIP SO400M, EGA improves Label Precision@1 by 4.75 and 8.55 percentage points.

## 1 Introduction

Modern retrieval systems increasingly rely on embedding models such as CLIP [25] for their remarkable zero-shot semantic capabilities. These models provide highly generalizable latent spaces that serve as excellent starting points for vector similarity search [16]. When deploying these systems to specialized domains, practitioners often seek to further align the embeddings with domain-specific category structures to maximize retrieval accuracy. However, full-scale fine-tuning is computationally prohibitive and risks destroying the foundational zero-shot knowledge. As a result, parameter-efficient adaptation, i.e., training lightweight adapters on a labeled subset while keeping the massive pre-trained backbone frozen, has become the prevailing paradigm.

Yet this paradigm harbors a fundamental limitation that is frequently overlooked: retrieval systems must serve queries from *unseen* categories that never appeared during adapter training. Both the database and the query stream inevitably contain classes absent from the labeled subset, and the adapter is expected to support meaningful retrieval over these unseen classes. Existing methods fail to meet this requirement. Global contrastive objectives such as ICon [1] and SRL [4] aggressively optimize for seen-class structure by computing losses over the full pairwise similarity matrix, with no mechanism to preserve the embedding geometry of unseen categories. Low-rank adapters such as

Submitted to 40th Conference on Neural Information Processing Systems (NeurIPS 2026). Do not distribute.

LoRA [10] avoid catastrophic collapse on unseen classes but are inherently capacity-limited, resulting in weak in-distribution performance. Together, these approaches reveal a structural in-distribution/out-of-distribution (ID/OOD) tradeoff rather than delivering uniformly improved adapters.

We demonstrate this tradeoff empirically. On in-distribution data (CIFAR-100), high-capacity global contrastive adapters achieve near-perfect Label Precision: ICon reaches $0.999$ and SRL reaches $0.992$ at $K = 1$, nprobe $= 1$. On the strictly unseen classes of Food-101, however, the same adapters collapse to $0.562$ and $0.552$, a drop of $44$ percentage points from their in-distribution scores and 32 to 33 percentage points below the frozen CLIP baseline. LoRA variants avoid this collapse but suffer a different limitation: their in-distribution Label Precision is bounded around $0.61$–$0.67$, substantially below what high-capacity adapters can achieve when overfitting is not penalized by distribution shift.

We propose Euclidean Geodesic Alignment (EGA), a manifold-preserving adapter that strikes a Pareto-optimal balance between in-distribution precision and out-of-distribution robustness. EGA admits three design choices: a zero-initialized residual structure, $\ell_2$ normalization, and a small-margin triplet loss on the class-aware neighborhood graph. The small-margin triplet loss induces a self-limiting dynamic: as the adapter converges on seen classes, the fraction of margin-violating triplets decays rapidly, reaching $96.5\%$ zero-gradient triplets at steady state. This allows the high-capacity architecture to tightly refine seen-class regions while staying largely inactive elsewhere, thereby protecting the pre-trained semantic structure of unseen categories from the dense global reshaping that causes ICon and SRL to fail on OOD data.

We evaluate EGA on CIFAR-100 (in-distribution) and three OOD benchmarks (CIFAR-10, FGVC-Aircraft, Food-101), comparing against the frozen CLIP baseline, global contrastive adapters (ICon, SRL), and two LoRA configurations (LoRA+InfoNCE, LoRA+Triplet). The six methods trace out a Pareto frontier in the (ID, OOD) Label Precision plane. EGA occupies a distinct operating point on this frontier: it reaches $0.705$ in-distribution Label Precision (within $30$ percentage points of the ICon/SRL ceiling and $4$ to $9$ percentage points above the LoRA variants), while improving over the frozen baseline on Aircraft ($+9.9$ pp) and bounding the degradation on CIFAR-10 ($-7.0$ pp) and Food-101 ($-9.0$ pp, versus $-32$ to $-33$ pp for ICon and SRL on Food-101). These benefits generalize consistently from the classic CLIP model [25] to more recentbackbones: on DINOv2-large [23] and SigLIP [39], EGA further improves Label Precision@1 by $4.75$ and $8.55$ percentage points, respectively. Different points on this frontier suit different deployment scenarios: applications that prioritize in-distribution precision benefit from EGA's balanced position, while applications dominated by OOD queries may prefer the higher OOD precision of low-capacity LoRA variants at the cost of in-distribution refinement.

In summary, this work makes the following contributions:

- We identify an ID/OOD tradeoff in adapter tuning for retrieval: high-capacity global contrastive objectives achieve near-perfect in-distribution precision but collapse on unseen classes, while low-capacity alternatives avoid collapse but underperform in-distribution.
- We propose Euclidean Geodesic Alignment (EGA), a residual adapter trained with a small-margin triplet loss that converges to a sparse-gradient scheme, preserving unseen-class geometry while refining seen-class structure.
- Across CIFAR-100 and three OOD benchmarks, EGA occupies a distinct Pareto-optimal point that balances in-distribution precision and out-of-distribution robustness, outperforming both global contrastive methods and low-capacity LoRA variants on respective axes.

## 2 Related Work

**Manifold Preservation under Adapter Tuning** Foundation models such as CLIP [25] produce embedding spaces that encode both seen-class semantics and broader priors over unseen visual concepts. Catastrophic forgetting has been studied extensively in continual learning [20, 37], while recent work documents analogous degradation in contrastive representations, including anisotropic collapse [43, 6], modality gap fracturing [26, 5], and loss of compositional structure [24, 28, 36]. Recent strategies counter these issues with geometric constraints such as orthogonality regularization [27]. *EGA leverages the inherent sparsity of triplet loss optimization to confine adapter updates to local neighborhoods of seen classes, leaving the unseen class regions of the pretrained manifold structurally unmodified.*

**Global Contrastive Objectives and Structural Regularization** Recent representation learning frequently relies on global contrastive objectives to optimize the latent space [31, 19]. A common paradigm jointly enforces alignment for positive pairs and uniformity across the feature distribution [34], a strategy applied in graph encoders [33] and multimodal recommendation [44]. While uniformity improves robustness to noise [35], it assumes uniform treatment of all latent regions. Auxiliary structural regularizers include unifying frameworks for multi-view alignment [1], geometric constraints for imbalanced regression [4], decoupled objectives [18], information-theoretic density control [42], and region-based distillation [15]. *EGA replaces dense global optimization with sparse local triplet updates, preserving out of distribution semantic structure.*

**Parameter-Efficient Manifold Adaptation** Parameter-efficient adaptation has become the standard approach to prevent catastrophic forgetting and reduce computational cost when transferring large foundation models [9, 10]. This paradigm now dominates vision-language research due to the prohibitive cost of full fine-tuning [21]. Lightweight methods such as Visual Prompt Tuning [14] and Tip Adapter [41] enable effective specialization without modifying the frozen backbone, and extensive benchmarks show they can rival full fine-tuning while preserving generalization [29]. Zero-initialization strategies further protect the pretrained manifold [40]. *EGA integrates a zero initialized residual adapter with a localized geometric objective, achieving both parameter efficiency and targeted manifold smoothing.*

**Vector Similarity Search and Metric Consistency** Vector similarity search is the foundational engine for scalable high-dimensional retrieval. The systems community has developed highly optimized indexing algorithms for billion-scale datasets, including FAISS [16], Hierarchical Navigable Small World graphs [22], DiskANN [30], and SPANN [2]. Recent work refines graph topologies [38, 3], optimizes SSD-based search [7, 8], and accelerates distance computations [13]. Nevertheless, popular ANN implementations still suffer from severe worst-case limitations [12]. *EGA proactively recalibrates the metric manifold prior to index construction, enabling standard search backends to achieve superior semantic recall without requiring complex algorithmic reengineering.*

# 3 Methodology

## 3.1 Problem Formulation

Let $\phi : \mathcal{X} \to \mathbb{R}^d$ denote a frozen vision-language encoder (e.g., CLIP ViT-B/32) that maps an image $x \in \mathcal{X}$ to a unit-normalized embedding $\mathbf{z} = \phi(x) \in \mathbb{S}^{d-1}$. We are given a set of labeled training images $\mathcal{D}_{\text{train}} = \{(x_i, y_i)\}_{i=1}^{N}$, where $y_i \in \mathcal{Y}_{\text{seen}}$ belongs to a set of *seen* classes. At inference time, the retrieval system must operate over a database that also contains images from a disjoint set of *unseen* classes $\mathcal{Y}_{\text{unseen}}$, with $\mathcal{Y}_{\text{seen}} \cap \mathcal{Y}_{\text{unseen}} = \emptyset$. Our goal is to learn an adapter $f_\theta : \mathbb{S}^{d-1} \to \mathbb{S}^{d-1}$ such that the transformed embeddings $\hat{\mathbf{z}} = f_\theta(\mathbf{z})$ support more accurate approximate nearest neighbor (ANN) retrieval on *both* seen and unseen classes, without access to unseen-class labels during training.

We evaluate retrieval quality along two complementary dimensions. *Label Precision*$@K$ (LP@K) measures the semantic quality of retrieved results: whether the $K$ nearest neighbors in the transformed space share the same class label as the query:

$$\text{LP}@K = \frac{1}{|\mathcal{Q}|} \sum_{q \in \mathcal{Q}} \frac{1}{K} \sum_{k=1}^{K} \mathbf{1}\left[y_{\hat{n}_k(q)} = y_q\right], \tag{1}$$

where $\mathcal{Q}$ is the query set and $\hat{n}_k(q)$ denotes the $k$-th nearest neighbor of $q$ in the transformed embedding space. *ANNS Recall*$@K$ (AR@K) measures the geometric fidelity of the ANN index, i.e, the fraction of true $K$ nearest neighbors (under exact search) that are recovered by the approximate index at a given search budget nprobe:

$$\text{AR}@K = \frac{1}{|\mathcal{Q}|} \sum_{q \in \mathcal{Q}} \frac{\left|\mathcal{N}_K^{\text{exact}}(q) \cap \mathcal{N}_K^{\text{approx}}(q)\right|}{K}, \tag{2}$$

where $\mathcal{N}_K^{\text{exact}}(q)$ and $\mathcal{N}_K^{\text{approx}}(q)$ denote the exact and approximate top-$K$ neighbor sets, respectively. The two metrics capture distinct failure modes: an adapter may improve LP$@K$ by tightening within-class clusters (semantic improvement) while simultaneously improving AR$@K$ by making the geometry more amenable to IVF-based indexing (geometric improvement).

### 3.2 Manifold-Preserving Adapter Design

EGA introduces a lightweight adapter $f_\theta$ composed of stacked residual blocks with a final refinement layer. The architecture is constrained by three design principles, each of which serves a distinct role in preserving the pretrained manifold.

**(1) Residual connection with zero initialization** Each EGA block applies a residual update as:

$$\mathbf{z}' = \mathbf{z} + g_\theta(\mathbf{z}), \tag{3}$$

where $g_\theta$ is a learned transformation initialized so that $g_\theta(\mathbf{z}) \approx \mathbf{0}$ at the start of training. Concretely, the final linear layer of $g_\theta$ is initialized to zero, making $f_\theta$ an identity mapping at initialization. This guarantees that training begins from the pretrained geometry rather than a random perturbation, and that the adapter can only *refine* rather than replace the CLIP embedding. As confirmed by our ablation (Table 3), removing the residual connection causes accuracy to collapse from $0.70$ to $0.01$, because the lightweight MLP cannot reconstruct complex semantic relationships from seen-class data alone.

**(2) Feature gating** Inside each residual block, the transformed signal passes through a module:

$$\mathrm{Gate}(\mathbf{h}) = \mathbf{h} \odot \sigma(W_2\, \mathrm{GELU}(W_1\mathbf{h}))\,, \tag{4}$$

where $W_1 \in \mathbb{R}^{(d/4)\times d}$, $W_2 \in \mathbb{R}^{d\times(d/4)}$, $\sigma$ is the Sigmoid function, and $\odot$ denotes elementwise multiplication. This structure, analogous to Squeeze-and-Excitation networks [11], learns a per-dimension importance weight that amplifies retrieval-relevant dimensions and suppresses noisy ones. The bottleneck ratio of $1/4$ is chosen to prevent the gating network from overfitting on seen-class data, as validated in Table 4.

The output of $f_\theta$ is projected back onto the unit hypersphere $\mathbb{S}^{d-1}$ via $\ell_2$:

$$\hat{\mathbf{z}} = \frac{f_\theta(\mathbf{z})}{\|f_\theta(\mathbf{z})\|_2}. \tag{5}$$

This constraint ensures that the transformed embeddings remain in the same metric space as the original CLIP embeddings, so that Euclidean distance and cosine similarity remain interchangeable on the hypersphere. Removing this constraint degrades retrieval performance by $4.2$ percentage points (Table 3), confirming that hypersphere consistency is necessary for stable ANN indexing.

**(3) Full forward pass** Let $\mathrm{Block}_i$ denote the $i$-th EGA block consisting of a two-layer MLP with LayerNorm followed by feature gating, and let Refine denote the final linear projection with LayerNorm. The complete forward pass for an input embedding $\mathbf{z} \in \mathbb{S}^{d-1}$ is:

$$\hat{\mathbf{z}} = \ell_2(\mathrm{Refine}(\mathrm{Block}_2(\mathrm{Block}_1(\mathbf{z}))))\,. \tag{6}$$

The total number of trainable parameters is approximately $4.2M$ for $d = 512$ and hidden dimension 2048, which is negligible compared to the frozen CLIP backbone ($\sim$150M parameters).

### 3.3 Local Triplet Training and Gradient Sparsity

Given a mini-batch $\mathcal{B}$ sampled from $\mathcal{D}_{\text{train}}$, we construct triplets $(a, p, n)$ where $a$ is an anchor image, $p$ is a positive sampled uniformly from the same class as $a$, and $n$ is a negative sampled uniformly from a different class. The adapter is trained with the standard triplet margin loss:

$$\mathcal{L} = \frac{1}{|\mathcal{B}|} \sum_{(a,p,n)\in\mathcal{B}} \max(0,\ d(\hat{\mathbf{z}}_a, \hat{\mathbf{z}}_p) - d(\hat{\mathbf{z}}_a, \hat{\mathbf{z}}_n) + m)\,, \tag{7}$$

where $d(\cdot,\cdot)$ denotes Euclidean distance, $m > 0$ is the margin hyperparameter, and $\hat{\mathbf{z}} = f_\theta(\mathbf{z})$ is the transformed embedding.

A triplet $(a, p, n)$ contributes a non-zero gradient to $\theta$ if and only if the margin constraint is *violated*:

$$d(\hat{\mathbf{z}}_a, \hat{\mathbf{z}}_p) - d(\hat{\mathbf{z}}_a, \hat{\mathbf{z}}_n) + m > 0. \tag{8}$$

We refer to such triplets as *active*. As the adapter converges on seen classes, increasingly many triplets satisfy the margin constraint and become inactive, contributing zero gradient. This sparsity has a direct consequence for out-of-distribution generalization. Because unseen classes are absent from $\mathcal{D}_{\text{train}}$, no triplet involving an unseen-class embedding is ever constructed. Provided that the adapter's updates remain effectively local (i.e., the cumulative perturbation induced by seen-class training gradients remains small in unseen-class regions of the embedding space), the manifold structure for unseen classes is largely preserved. The gradient sparsity mechanism enforces this locality: once seen-class neighborhoods satisfy the margin, the corresponding gradients vanish, and only the small fraction of actively-violated local relationships continue to be updated.

We formalize these intuitions in the following observation, which characterizes the steady-state behavior of triplet-trained adapters and its implications for manifold preservation.

**Observation 1** (Gradient Sparsity at Convergence)**.** *Let $f_\theta$ be trained with the triplet loss in Eq.* (7) *with margin $m > 0$ on a dataset $\mathcal{D}_{train}$ drawn from seen classes $\mathcal{Y}_{seen}$. Define the* active triplet ratio *at training step $t$ as*

$$\rho(t) = \Pr_{(a,p,n)\sim\mathcal{B}}\left[d\left(\hat{\mathbf{z}}_a^{(t)}, \hat{\mathbf{z}}_p^{(t)}\right) - d\left(\hat{\mathbf{z}}_a^{(t)}, \hat{\mathbf{z}}_n^{(t)}\right) + m > 0\right]. \tag{9}$$

*As $f_\theta$ converges, $\rho(t) \to \rho^*$, where*

$$\rho^* = \Pr_{(a,p,n)}\left[d\left(\hat{\mathbf{z}}_a^*, \hat{\mathbf{z}}_p^*\right) - d\left(\hat{\mathbf{z}}_a^*, \hat{\mathbf{z}}_n^*\right) + m > 0\right] \tag{10}$$

*is determined solely by the margin $m$ and the within-class distance distribution of the converged embeddings. Furthermore, $\nabla_\theta \mathcal{L} = \mathbf{0}$ for all triplets $(a, p, n)$ with $d(\hat{\mathbf{z}}_a^*, \hat{\mathbf{z}}_p^*) - d(\hat{\mathbf{z}}_a^*, \hat{\mathbf{z}}_n^*) + m \le 0$, so the adapter gradient is supported only on the fraction $\rho^*$ of the training distribution. For embeddings whose local geometry already satisfies the margin constraint, the adapter exerts zero update pressure.*

*Justification.* The triplet loss consists of hinge terms whose gradient is zero whenever the margin constraint is satisfied. At convergence, only those triplets whose geometry the adapter has not yet separated within the margin remain active. The fraction of such triplets is determined solely by the margin $m$ and the distance distribution of seen classes, independent of unseen classes. Since no training triplet involves unseen-class embeddings, the adapter exerts zero gradient over the entire unseen-class region of the embedding space. See Appendix A for the complete argument. $\square$

# 4 Evaluation

Experiments were conducted on the Chameleon Cloud platform using a compute node equipped with 256 AMD EPYC-7763 CPU cores, 512 GiB of RAM, and an NVIDIA A100 GPU of 80 GB HBM2e. Evaluation datasets include CIFAR-100 for in distribution scenarios, CIFAR-10 for cross dataset OOD settings, and FGVC-Aircraft and Food-101 for unseen class OOD evaluations. All of these datasets can be directly downloaded from the Pytorch library. We compare our method against four baseline models: ICon [1], SRL [4], LoRA + InfoNCE [10, 32], and LoRA + Triplet [10].

Extended experimental details can be found in Appendix B.

## 4.1 In-Distribution Validation

Figure 1 reports Label Precision@$K$ across four neighborhood sizes and three search budgets. EGA improves Label Precision@1 from $0.549$ (raw CLIP) to $0.705$ at nprobe $= 1$, and the gap persists across all $K$ and nprobe values. The improvement is not an artifact of larger search budgets: even at nprobe $= 10$, EGA retains a clear advantage: the adapter tightens within-class neighborhoods rather than benefiting from broader index coverage.

The Label Precision improvement has a direct geometric correlate. Figure 2 contrasts the $L_2$ distance distributions for true Top-$K$ neighbors against random background points, before and after EGA. In the raw CLIP space, the two distributions overlap substantially: the distance to a true neighbor is often indistinguishable from the distance to an unrelated point, which is exactly the condition under which IVF-based ANN indexing degrades. After EGA, the two distributions separate cleanly across all $K$, with neighbors concentrated at small distances and background points pushed toward a distinct mode. This separation is the mechanism by which EGA improves the recall-efficiency frontier shown in Figure 3: the raw CLIP space achieves only $0.667$ Recall@1 at nprobe $= 1$, whereas EGA reaches $0.825$ and saturates above $0.99$ by nprobe $= 5$.

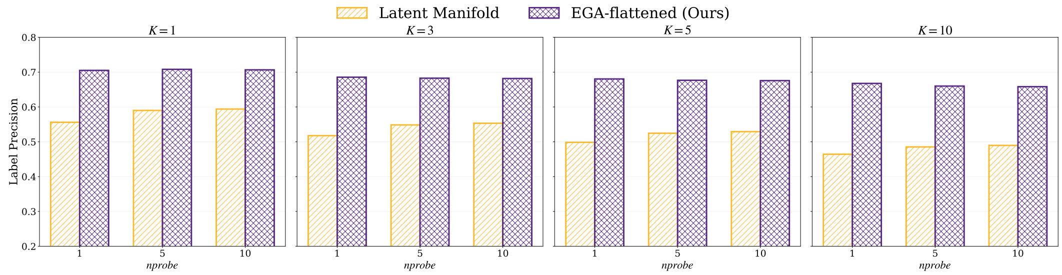

Figure 1: Label Precision@$K$ on CIFAR-100 across $K \in \{1, 3, 5, 10\}$ and nprobe $\in \{1, 5, 10\}$.

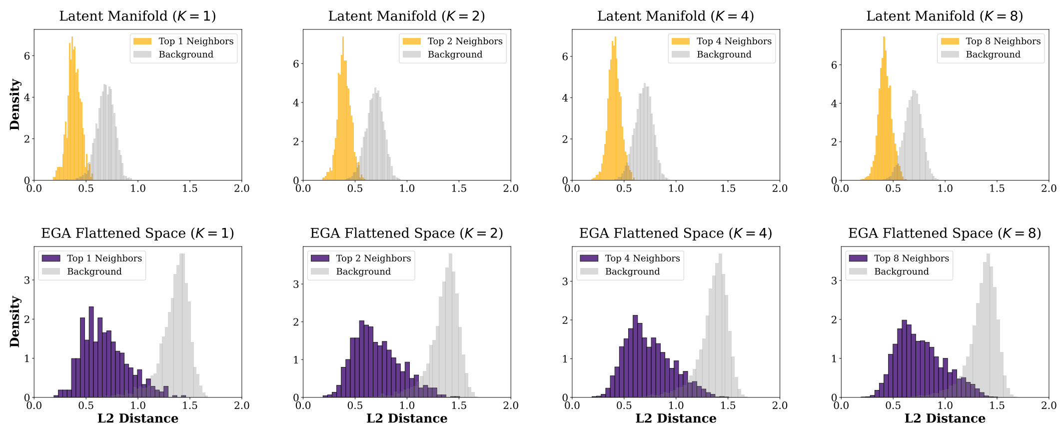

Figure 2: Distance distributions for Top-$K$ neighbors vs. random background points on CIFAR-100.

While Figures 1–3 focus on the EGA-vs-frozen contrast that underlies our geometric story, we also report all six methods' in-distribution performance in Table 1, since the contrast with their out-of-distribution behavior (Section 4.2) is central to our analysis. ICon and SRL achieve near-perfect Label Precision ($0.999$ and $0.992$ respectively) by maximally tightening seen-class clusters with their global contrastive objectives. EGA reaches LP@1 of $0.705$, an improvement of $+16$ pp over the frozen baseline; the LoRA variants land between EGA and the baseline. As we show in Section 4.2, the same property that allows ICon and SRL to dominate this in-distribution metric is what causes their catastrophic out-of-distribution collapse.

### 4.2 Out-of-Distribution Generalization

Under strict OOD settings where evaluation categories are disjoint from training categories, the two retrieval metrics tell different stories about adapter quality, and EGA is the only method that performs well on both. Table 2 reports headline numbers at $K = 1$, nprobe $= 1$. Figure 4 visualizes the joint (ID, OOD) tradeoff across all six methods, and Appendix C verifies that the pattern is robust across search budgets (nprobe $\in \{1, 5, 10\}$). We evaluate on three benchmarks: CIFAR-10 (trained on CIFAR-100), FGVC-Aircraft (80 seen / 20 unseen classes), and Food-101 (80 seen / 21 unseen classes). For a fair comparison, all methods train identical lightweight adapters on top of frozen CLIP features and differ only in their loss functions.

On ANNS Recall, the adapters either match or exceed the frozen CLIP baseline on Aircraft and Food-101, indicating that adapter training succeeds at geometric reorganization on these two benchmarks. On Label Precision, however, the picture inverts. ICon and SRL fall *below* the frozen CLIP baseline on every dataset, with degradation reaching $-32$ to $-33$ percentage points on Food-101. The retrieved neighbors are geometrically closer in the IVF index, but they belong to the wrong semantic class. EGA improves Label Precision over the frozen baseline on Aircraft ($+9.9$ pp), with bounded degradation on CIFAR-10 ($-7.0$ pp) and Food-101 ($-9.0$ pp). The corresponding collapse for ICon and SRL is much larger: $-32$ to $-33$ pp on Food-101 and $-32$ to $-34$ pp on CIFAR-10.

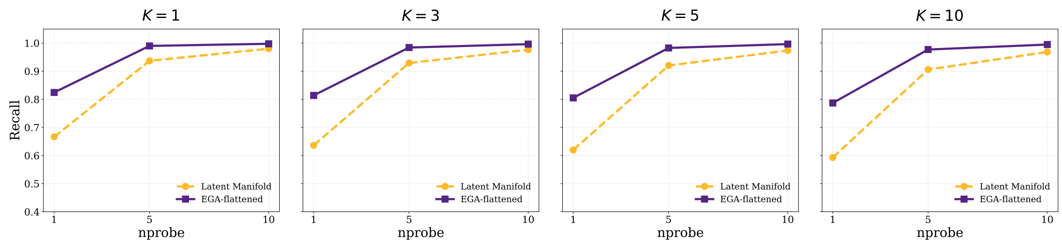

Figure 3: ANNS Recall@$K$ versus nprobe on CIFAR-100.

Table 1: In-distribution retrieval performance on CIFAR-100 at $K = 1$, nprobe $= 1$.

| Metric | CLIP | ICon | SRL | LoRA+InfoNCE | LoRA+Triplet | EGA |
|---|---|---|---|---|---|---|
| LP@1 | 0.549 | **0.999** | **0.992** | **0.668** | **0.612** | **0.705** |
| AR@1 | 0.667 | **0.992** | **0.991** | **0.879** | **0.908** | **0.825** |

EGA's relative advantage over global methods ranges from $14$ pp on Aircraft to $23$ pp on Food-101 and $25$ pp on CIFAR-10, and tracks the difficulty of the OOD shift: when seen and unseen classes are visually similar (as in Food-101's fine-grained dishes), the dense gradient updates of ICon and SRL pull unseen samples most aggressively into the wrong seen-class clusters. Robustness across search budgets (nprobe $\in \{1, 5, 10\}$) is reported in Appendix C.

Cross-referencing Table 1 and Table 2 reveals a structural tradeoff among adapter training paradigms. ICon and SRL achieve near-perfect Label Precision on CIFAR-100 ($0.999$ and $0.992$) but collapse to $0.562$ and $0.552$ on Food-101. The frozen baseline and LoRA variants sit at the opposite extreme: modest in-distribution precision ($0.55$ to $0.67$) but stable performance under distribution shift. EGA occupies a balanced position: $0.705$ in-distribution and $0.791$ on Food-101, with $0.611$ on Aircraft and $0.810$ on CIFAR-10.

The six methods we evaluate trace out a Pareto frontier in the (ID Label Precision, OOD Label Precision) plane, in Figure 4. The dashed line interpolates between non-dominated points (those for which no other method achieves both higher ID and higher OOD Label Precision). ICon and SRL achieve the highest in-distribution precision but collapse on OOD; the LoRA variants achieve competitive OOD precision on Food-101 and CIFAR-10 but underperform EGA in-distribution by $4$ to $9$ percentage points. EGA occupies a distinct operating point on this frontier, combining the highest in-distribution precision among adapters that avoid OOD collapse with bounded OOD degradation.

We evaluate LoRA [10] as a parameter-efficient baseline (rank $r = 8$, $\sim$8K trainable parameters vs. $\sim$4.2M for the EGAMLP architecture used by EGA, ICon, and SRL). Two configurations are included: LoRA + InfoNCE (a global contrastive loss) and LoRA + Triplet (the same loss as EGA). Both LoRA configurations avoid the Label Precision collapse exhibited by ICon and SRL even when paired with a global loss: LoRA + InfoNCE on Food-101 reaches LP $0.883$, statistically indistinguishable from the frozen baseline ($0.881$, std $0.004$). This suggests that the failure of ICon and SRL arises from the *combination* of (i) full-capacity adapter and (ii) dense global gradients.

### 4.3 Two Mechanisms for OOD Stability

The OOD pattern in Section 4.2 raises a mechanistic question: why do some adapters preserve unseen-class structure while others reshape it under global contrastive objectives? As we will show, experiments suggest two distinct mechanisms for OOD stability, which place adapters at different operating points on the Pareto frontier. Formally, a triplet loss with margin $m$ produces a non-zero gradient for a sample triplet $(a, p, n)$ only when the margin constraint is violated, i.e., when

$$d(a, p) - d(a, n) + m > 0. \tag{11}$$

As the adapter converges on seen classes, the fraction of *active* triplets decays. Figure 5 (left) tracks this ratio throughout training: starting at $17.4\%$ at epoch 10, it falls to $3.5\%$ by convergence. At steady state, 96.5% of triplets contribute zero gradient, meaning the adapter updates a sparse subset of local neighborhood relationships and leaves the remainder of the embedding space intact.

Table 2: OOD performance at $K = 1$, nprobe $= 1$, mean $\pm$ std over 3 random seeds (42, 123, 456).

| Dataset | Metric | CLIP | ICon | SRL | LoRA+InfoNCE | LoRA+Triplet | EGA |
|---|---|---|---|---|---|---|---|
| CIFAR-10 | AR@1 | 0.863 | 0.797$\pm$.003 | 0.819$\pm$.001 | **0.869**$\pm$.012 | 0.861$\pm$.011 | 0.833$\pm$.005 |
| | LP@1 | 0.880 | 0.560$\pm$.010 | 0.536$\pm$.008 | **0.885**$\pm$.006 | 0.875$\pm$.006 | 0.810$\pm$.002 |
| Aircraft | AR@1 | 0.773 | **0.853**$\pm$.016 | **0.879**$\pm$.023 | **0.891**$\pm$.015 | **0.893**$\pm$.008 | **0.905**$\pm$.015 |
| | LP@1 | 0.512 | 0.470$\pm$.034 | 0.375$\pm$.032 | **0.538**$\pm$.020 | **0.569**$\pm$.011 | **0.611**$\pm$.020 |
| Food-101 | AR@1 | 0.842 | 0.821$\pm$.001 | 0.824$\pm$.015 | **0.906**$\pm$.003 | **0.893**$\pm$.008 | **0.879**$\pm$.011 |
| | LP@1 | 0.881 | 0.562$\pm$.011 | 0.552$\pm$.010 | 0.883$\pm$.004 | 0.833$\pm$.007 | 0.791$\pm$.002 |

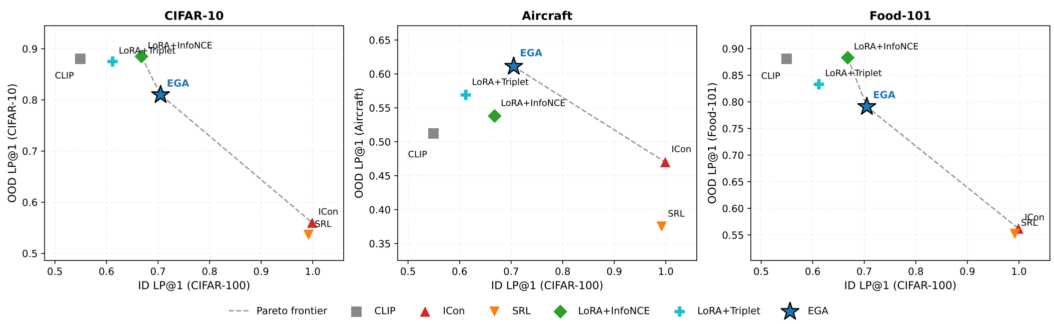

Figure 4: ID/OOD Pareto frontier of adapter training paradigms.

Global contrastive objectives such as ICon [1] and SRL [4] exhibit the opposite behavior. ICon minimizes a Kullback–Leibler (KL) divergence over the full pairwise similarity matrix, and SRL jointly optimizes batch-wide uniformity and homogeneity. Both produce *dense* gradient fields in every training step: every sample pair contributes to the loss regardless of whether its local geometry already satisfies the retrieval objective. This global optimization pressure shapes the entire embedding distribution based on seen-class similarities, even for regions of the space occupied by unseen-class samples. The result is not loss of geometric structure but rather loss of *semantically correct* structure: unseen samples are pulled toward the clusters of seen classes that they happen to resemble in CLIP's original metric, rather than toward other unseen samples that share their true category.

Figure 5 (right) and Table 2 together quantify the consequence: across all three OOD benchmarks, ICon and SRL fall below the frozen CLIP baseline on Label Precision (e.g., on Aircraft, ICon collapses to $0.470$ from a baseline of $0.512$), confirming that combining dense gradient fields with high adapter capacity harms zero-shot semantic retrieval. EGA, by contrast, improves Label Precision over the frozen baseline on Aircraft and bounds the degradation on the other two OOD benchmarks, while only $3.5\%$ of training triplets contribute non-zero gradients at convergence.

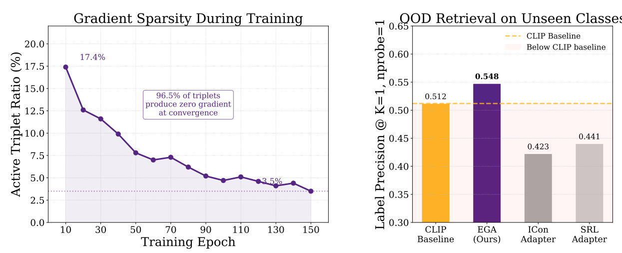

Figure 5: Gradient sparsity as OOD protection.

### 4.4 Ablation and Sensitivity Analysis

Table 3 isolates the contribution of each architectural component. The residual connection is the core element. Removing it causes accuracy to collapse from 0.7015 to 0.0065. This indicates that the adapter cannot reconstruct semantic relationships from target data alone and must operate as a refinement over the pre-trained features. The L2 normalization ensures the transformed embeddings remain on the unit hypersphere. Removing it decreases accuracy to 0.6590. Zero-initialization allows the adapter to begin training as an identity mapping; removing it lowers accuracy to 0.6840.

Table 4 evaluates model stability across hyperparameter variations. EGA maintains consistent quality across margins from 0.1 to 0.3. Increasing the margin to 0.5 degrades Recall@1 to 0.7400. A larger margin forces the adapter to update embeddings that already satisfy local neighborhood constraints,

Table 3: Ablation study of EGA

| Variant | Accuracy |
|---|---|
| Full EGA (Ours) | 0.7015 |
| w/o Residual connection | 0.0065 |
| w/o Zero-initialization | 0.6840 |
| w/o L2-normalization | 0.6590 |

Table 4: Sensitivity of different hyperparameters

| Triplet Margin $m$ | 0.1 | 0.2 | 0.3 | 0.5 |
|---|---|---|---|---|
| Recall@1 | 0.8420 | 0.8180 | 0.8160 | 0.7400 |
| Recall@5 | 0.9782 | 0.9654 | 0.9610 | 0.9125 |
| Hidden Dimension $d$ | 512 | 1024 | 2048 | 4096 |
| Recall@1 | 0.8300 | 0.8340 | 0.8200 | 0.8240 |
| Recall@5 | 0.9695 | 0.9712 | 0.9680 | 0.9688 |

which reduces gradient sparsity and alters the pre-trained manifold. Furthermore, the model shows stable performance across hidden dimensions from 512 to 4096. This stability confirms that EGA achieves metric correction through its structural design rather than specific parameters.

### 4.5 Generalization to Stronger Backbones

To verify that the benefits of EGA are not specific to the CLIP ViT-B/32 backbone used in our main experiments, we further evaluate EGA on two stronger and more recent vision encoders: DINOv2-large [23] and SigLIP [39].

As shown in Table 5, EGA delivers consistent improvements across all three backbones. On the relatively weaker CLIP ViT-B/32, EGA achieves substantial gains of +13.95 percentage points in Label Precision@1 and +13.20 percentage points in Recall@1. Even on the much stronger DINOv2-large and SigLIP backbones, EGA continues to provide meaningful and stable improvements (+4.75pp and +8.55pp in Label Precision@1, respectively). These results demonstrate that EGA's manifold-preserving design generalizes robustly to modern, high-capacity vision models and is not merely an artifact of the original CLIP representation.

Table 5: Retrieval performance on more backbones.

| Backbone | Label Precision@1 | | ANNS Recall@1 | |
|---|---|---|---|---|
| | Raw | +EGA | Raw | +EGA |
| CLIP ViT-B/32 | 0.5560 | **0.6955** | 0.6665 | **0.7985** |
| DINOv2-large | 0.8530 | **0.9005** | 0.8785 | **0.9310** |
| SigLIP SO400M | 0.7740 | **0.8595** | 0.8015 | **0.9155** |

## 5 Conclusion

Adapter training over frozen embedding models does not produce uniformly improved retrieval embeddings. Instead, different methods occupy different points on an in-distribution/out-of-distribution Pareto frontier. ICon and SRL reach near-perfect Label Precision on CIFAR-100 ($0.999$, $0.992$) but collapse 32 to 33 percentage points below the frozen baseline on Food-101, while low-capacity LoRA adapters avoid this collapse at the cost of substantial in-distribution underperformance. EGA occupies a distinct point on this frontier, reaching $0.705$ in-distribution Label Precision while bounding OOD degradation to $-7$ to $-9$ percentage points. These benefits generalize consistently to stronger vision backbones: on DINOv2-large and SigLIP, EGA further improves Label Precision@1 by $4.75$ and $8.55$ percentage points, respectively. The underlying mechanism is gradient sparsity at convergence ($96.5\%$ of training triplets produce zero gradient at steady state), which we suggest as a useful diagnostic for future adapter design. A more rigorous disentanglement of capacity and sparsity contributions is left for future work.

# NeurIPS Paper Checklist

1. **Claims**

   Question: Do the main claims made in the abstract and introduction accurately reflect the paper's contributions and scope?

   Answer: [Yes]

   Justification: The paper presents both theoretical and experimental evidence to support its claims.

   Guidelines:

   - The answer [N/A] means that the abstract and introduction do not include the claims made in the paper.
   - The abstract and/or introduction should clearly state the claims made, including the contributions made in the paper and important assumptions and limitations. A [No] or [N/A] answer to this question will not be perceived well by the reviewers.
   - The claims made should match theoretical and experimental results, and reflect how much the results can be expected to generalize to other settings.
   - It is fine to include aspirational goals as motivation as long as it is clear that these goals are not attained by the paper.

2. **Limitations**

   Question: Does the paper discuss the limitations of the work performed by the authors?

   Answer: [Yes]

   Justification: We discuss the limitations of our approach in the conclusion.

   Guidelines:

   - The answer [N/A] means that the paper has no limitation while the answer [No] means that the paper has limitations, but those are not discussed in the paper.
   - The authors are encouraged to create a separate "Limitations" section in their paper.
   - The paper should point out any strong assumptions and how robust the results are to violations of these assumptions (e.g., independence assumptions, noiseless settings, model well-specification, asymptotic approximations only holding locally). The authors should reflect on how these assumptions might be violated in practice and what the implications would be.
   - The authors should reflect on the scope of the claims made, e.g., if the approach was only tested on a few datasets or with a few runs. In general, empirical results often depend on implicit assumptions, which should be articulated.
   - The authors should reflect on the factors that influence the performance of the approach. For example, a facial recognition algorithm may perform poorly when image resolution is low or images are taken in low lighting. Or a speech-to-text system might not be used reliably to provide closed captions for online lectures because it fails to handle technical jargon.
   - The authors should discuss the computational efficiency of the proposed algorithms and how they scale with dataset size.
   - If applicable, the authors should discuss possible limitations of their approach to address problems of privacy and fairness.
   - While the authors might fear that complete honesty about limitations might be used by reviewers as grounds for rejection, a worse outcome might be that reviewers discover limitations that aren't acknowledged in the paper. The authors should use their best judgment and recognize that individual actions in favor of transparency play an important role in developing norms that preserve the integrity of the community. Reviewers will be specifically instructed to not penalize honesty concerning limitations.

3. **Theory assumptions and proofs**

   Question: For each theoretical result, does the paper provide the full set of assumptions and a complete (and correct) proof?

   Answer: [Yes]

Justification: Full proofs are provided in the appendix, and all assumptions are clearly stated in the main paper and/or the appendix.

Guidelines:

- The answer [N/A] means that the paper does not include theoretical results.
- All the theorems, formulas, and proofs in the paper should be numbered and cross-referenced.
- All assumptions should be clearly stated or referenced in the statement of any theorems.
- The proofs can either appear in the main paper or the supplemental material, but if they appear in the supplemental material, the authors are encouraged to provide a short proof sketch to provide intuition.
- Inversely, any informal proof provided in the core of the paper should be complemented by formal proofs provided in appendix or supplemental material.
- Theorems and Lemmas that the proof relies upon should be properly referenced.

4. **Experimental result reproducibility**

Question: Does the paper fully disclose all the information needed to reproduce the main experimental results of the paper to the extent that it affects the main claims and/or conclusions of the paper (regardless of whether the code and data are provided or not)?

Answer: [Yes]

Justification: All code and data needed to reproduce the main experimental results are availabe on the anonymous Github repository.

Guidelines:

- The answer [N/A] means that the paper does not include experiments.
- If the paper includes experiments, a [No] answer to this question will not be perceived well by the reviewers: Making the paper reproducible is important, regardless of whether the code and data are provided or not.
- If the contribution is a dataset and/or model, the authors should describe the steps taken to make their results reproducible or verifiable.
- Depending on the contribution, reproducibility can be accomplished in various ways. For example, if the contribution is a novel architecture, describing the architecture fully might suffice, or if the contribution is a specific model and empirical evaluation, it may be necessary to either make it possible for others to replicate the model with the same dataset, or provide access to the model. In general. releasing code and data is often one good way to accomplish this, but reproducibility can also be provided via detailed instructions for how to replicate the results, access to a hosted model (e.g., in the case of a large language model), releasing of a model checkpoint, or other means that are appropriate to the research performed.
- While NeurIPS does not require releasing code, the conference does require all submissions to provide some reasonable avenue for reproducibility, which may depend on the nature of the contribution. For example
  (a) If the contribution is primarily a new algorithm, the paper should make it clear how to reproduce that algorithm.
  (b) If the contribution is primarily a new model architecture, the paper should describe the architecture clearly and fully.
  (c) If the contribution is a new model (e.g., a large language model), then there should either be a way to access this model for reproducing the results or a way to reproduce the model (e.g., with an open-source dataset or instructions for how to construct the dataset).
  (d) We recognize that reproducibility may be tricky in some cases, in which case authors are welcome to describe the particular way they provide for reproducibility. In the case of closed-source models, it may be that access to the model is limited in some way (e.g., to registered users), but it should be possible for other researchers to have some path to reproducing or verifying the results.

5. **Open access to data and code**

Question: Does the paper provide open access to the data and code, with sufficient instructions to faithfully reproduce the main experimental results, as described in supplemental material?

Answer: [Yes]

Justification: All the details to reproduce the main experimental results are provided in the anonymous Github repository, including instructions for data access and preparation, and scripts to reproduce all experimental results for the new proposed method and baselines.

Guidelines:

- The answer [N/A] means that paper does not include experiments requiring code.
- Please see the NeurIPS code and data submission guidelines (`https://neurips.cc/public/guides/CodeSubmissionPolicy`) for more details.
- While we encourage the release of code and data, we understand that this might not be possible, so [No] is an acceptable answer. Papers cannot be rejected simply for not including code, unless this is central to the contribution (e.g., for a new open-source benchmark).
- The instructions should contain the exact command and environment needed to run to reproduce the results. See the NeurIPS code and data submission guidelines (`https://neurips.cc/public/guides/CodeSubmissionPolicy`) for more details.
- The authors should provide instructions on data access and preparation, including how to access the raw data, preprocessed data, intermediate data, and generated data, etc.
- The authors should provide scripts to reproduce all experimental results for the new proposed method and baselines. If only a subset of experiments are reproducible, they should state which ones are omitted from the script and why.
- At submission time, to preserve anonymity, the authors should release anonymized versions (if applicable).
- Providing as much information as possible in supplemental material (appended to the paper) is recommended, but including URLs to data and code is permitted.

6. **Experimental setting/details**

Question: Does the paper specify all the training and test details (e.g., data splits, hyperparameters, how they were chosen, type of optimizer) necessary to understand the results?

Answer: [Yes]

Justification: All such details are provided in the anonymous Github repository, and the main paper includes a summary of the experimental setting.

Guidelines:

- The answer [N/A] means that the paper does not include experiments.
- The experimental setting should be presented in the core of the paper to a level of detail that is necessary to appreciate the results and make sense of them.
- The full details can be provided either with the code, in appendix, or as supplemental material.

7. **Experiment statistical significance**

Question: Does the paper report error bars suitably and correctly defined or other appropriate information about the statistical significance of the experiments?

Answer: [Yes]

Justification: The results are pretty stable so we did not report error bars; we explain this in the main paper.

Guidelines:

- The answer [N/A] means that the paper does not include experiments.
- The authors should answer [Yes] if the results are accompanied by error bars, confidence intervals, or statistical significance tests, at least for the experiments that support the main claims of the paper.

- The factors of variability that the error bars are capturing should be clearly stated (for example, train/test split, initialization, random drawing of some parameter, or overall run with given experimental conditions).
- The method for calculating the error bars should be explained (closed form formula, call to a library function, bootstrap, etc.)
- The assumptions made should be given (e.g., Normally distributed errors).
- It should be clear whether the error bar is the standard deviation or the standard error of the mean.
- It is OK to report 1-sigma error bars, but one should state it. The authors should preferably report a 2-sigma error bar than state that they have a 96% CI, if the hypothesis of Normality of errors is not verified.
- For asymmetric distributions, the authors should be careful not to show in tables or figures symmetric error bars that would yield results that are out of range (e.g., negative error rates).
- If error bars are reported in tables or plots, the authors should explain in the text how they were calculated and reference the corresponding figures or tables in the text.

8. **Experiments compute resources**

   Question: For each experiment, does the paper provide sufficient information on the computer resources (type of compute workers, memory, time of execution) needed to reproduce the experiments?

   Answer: [Yes]

   Justification: These details are provided in the anonymous Github repository, and the main paper includes a summary of the compute resources used for the experiments.

   Guidelines:

   - The answer [N/A] means that the paper does not include experiments.
   - The paper should indicate the type of compute workers CPU or GPU, internal cluster, or cloud provider, including relevant memory and storage.
   - The paper should provide the amount of compute required for each of the individual experimental runs as well as estimate the total compute.
   - The paper should disclose whether the full research project required more compute than the experiments reported in the paper (e.g., preliminary or failed experiments that didn't make it into the paper).

9. **Code of ethics**

   Question: Does the research conducted in the paper conform, in every respect, with the NeurIPS Code of Ethics `https://neurips.cc/public/EthicsGuidelines`?

   Answer: [Yes]

   Justification: We believe we have followed the NeurIPS Code of Ethics in all aspects of our research.

   Guidelines:

   - The answer [N/A] means that the authors have not reviewed the NeurIPS Code of Ethics.
   - If the authors answer [No], they should explain the special circumstances that require a deviation from the Code of Ethics.
   - The authors should make sure to preserve anonymity (e.g., if there is a special consideration due to laws or regulations in their jurisdiction).

10. **Broader impacts**

    Question: Does the paper discuss both potential positive societal impacts and negative societal impacts of the work performed?

    Answer: [N/A]

    Justification: [N/A]

    Guidelines:

- The answer [N/A] means that there is no societal impact of the work performed.
- If the authors answer [N/A] or [No], they should explain why their work has no societal impact or why the paper does not address societal impact.
- Examples of negative societal impacts include potential malicious or unintended uses (e.g., disinformation, generating fake profiles, surveillance), fairness considerations (e.g., deployment of technologies that could make decisions that unfairly impact specific groups), privacy considerations, and security considerations.
- The conference expects that many papers will be foundational research and not tied to particular applications, let alone deployments. However, if there is a direct path to any negative applications, the authors should point it out. For example, it is legitimate to point out that an improvement in the quality of generative models could be used to generate Deepfakes for disinformation. On the other hand, it is not needed to point out that a generic algorithm for optimizing neural networks could enable people to train models that generate Deepfakes faster.
- The authors should consider possible harms that could arise when the technology is being used as intended and functioning correctly, harms that could arise when the technology is being used as intended but gives incorrect results, and harms following from (intentional or unintentional) misuse of the technology.
- If there are negative societal impacts, the authors could also discuss possible mitigation strategies (e.g., gated release of models, providing defenses in addition to attacks, mechanisms for monitoring misuse, mechanisms to monitor how a system learns from feedback over time, improving the efficiency and accessibility of ML).

11. **Safeguards**

    Question: Does the paper describe safeguards that have been put in place for responsible release of data or models that have a high risk for misuse (e.g., pre-trained language models, image generators, or scraped datasets)?

    Answer: [N/A]

    Justification: [N/A]

    Guidelines:

    - The answer [N/A] means that the paper poses no such risks.
    - Released models that have a high risk for misuse or dual-use should be released with necessary safeguards to allow for controlled use of the model, for example by requiring that users adhere to usage guidelines or restrictions to access the model or implementing safety filters.
    - Datasets that have been scraped from the Internet could pose safety risks. The authors should describe how they avoided releasing unsafe images.
    - We recognize that providing effective safeguards is challenging, and many papers do not require this, but we encourage authors to take this into account and make a best faith effort.

12. **Licenses for existing assets**

    Question: Are the creators or original owners of assets (e.g., code, data, models), used in the paper, properly credited and are the license and terms of use explicitly mentioned and properly respected?

    Answer: [N/A]

    Justification: [N/A]

    Guidelines:

    - The answer [N/A] means that the paper does not use existing assets.
    - The authors should cite the original paper that produced the code package or dataset.
    - The authors should state which version of the asset is used and, if possible, include a URL.
    - The name of the license (e.g., CC-BY 4.0) should be included for each asset.
    - For scraped data from a particular source (e.g., website), the copyright and terms of service of that source should be provided.

- If assets are released, the license, copyright information, and terms of use in the package should be provided. For popular datasets, `paperswithcode.com/datasets` has curated licenses for some datasets. Their licensing guide can help determine the license of a dataset.
- For existing datasets that are re-packaged, both the original license and the license of the derived asset (if it has changed) should be provided.
- If this information is not available online, the authors are encouraged to reach out to the asset's creators.

13. **New assets**

    Question: Are new assets introduced in the paper well documented and is the documentation provided alongside the assets?

    Answer: [N/A]

    Justification: [N/A]

    Guidelines:

    - The answer [N/A] means that the paper does not release new assets.
    - Researchers should communicate the details of the dataset/code/model as part of their submissions via structured templates. This includes details about training, license, limitations, etc.
    - The paper should discuss whether and how consent was obtained from people whose asset is used.
    - At submission time, remember to anonymize your assets (if applicable). You can either create an anonymized URL or include an anonymized zip file.

14. **Crowdsourcing and research with human subjects**

    Question: For crowdsourcing experiments and research with human subjects, does the paper include the full text of instructions given to participants and screenshots, if applicable, as well as details about compensation (if any)?

    Answer: [N/A]

    Justification: [N/A]

    Guidelines:

    - The answer [N/A] means that the paper does not involve crowdsourcing nor research with human subjects.
    - Including this information in the supplemental material is fine, but if the main contribution of the paper involves human subjects, then as much detail as possible should be included in the main paper.
    - According to the NeurIPS Code of Ethics, workers involved in data collection, curation, or other labor should be paid at least the minimum wage in the country of the data collector.

15. **Institutional review board (IRB) approvals or equivalent for research with human subjects**

    Question: Does the paper describe potential risks incurred by study participants, whether such risks were disclosed to the subjects, and whether Institutional Review Board (IRB) approvals (or an equivalent approval/review based on the requirements of your country or institution) were obtained?

    Answer: [N/A]

    Justification: [N/A]

    Guidelines:

    - The answer [N/A] means that the paper does not involve crowdsourcing nor research with human subjects.
    - Depending on the country in which research is conducted, IRB approval (or equivalent) may be required for any human subjects research. If you obtained IRB approval, you should clearly state this in the paper.

- We recognize that the procedures for this may vary significantly between institutions and locations, and we expect authors to adhere to the NeurIPS Code of Ethics and the guidelines for their institution.
- For initial submissions, do not include any information that would break anonymity (if applicable), such as the institution conducting the review.

16. **Declaration of LLM usage**

    Question: Does the paper describe the usage of LLMs if it is an important, original, or non-standard component of the core methods in this research? Note that if the LLM is used only for writing, editing, or formatting purposes and does *not* impact the core methodology, scientific rigor, or originality of the research, declaration is not required.

    Answer: [N/A]

    Justification: [N/A]

    Guidelines:

    - The answer [N/A] means that the core method development in this research does not involve LLMs as any important, original, or non-standard components.
    - Please refer to our LLM policy in the NeurIPS handbook for what should or should not be described.

# A Justification of Observation 1

*Proof.* We justify each claim in turn.

**(1) Gradient support.** The triplet loss in Eq. (7) can be written as $\mathcal{L} = \frac{1}{|\mathcal{B}|}\sum_{(a,p,n)\in\mathcal{B}} \ell_{apn}$, where $\ell_{apn} = \max(0, \delta_{apn} + m)$ and $\delta_{apn} = d(\hat{\mathbf{z}}_a, \hat{\mathbf{z}}_p) - d(\hat{\mathbf{z}}_a, \hat{\mathbf{z}}_n)$. The subgradient with respect to $\theta$ is

$$\nabla_\theta \ell_{apn} = \mathbf{1}[\delta_{apn} + m > 0] \cdot \nabla_\theta \delta_{apn}, \tag{12}$$

which is exactly zero whenever $\delta_{apn} + m \leq 0$. Therefore, $\nabla_\theta \mathcal{L}$ receives contributions only from active triplets satisfying Eq. (8).

**(2) Convergence of $\rho(t)$.** Under mild regularity conditions (Lipschitz continuity of $f_\theta$ and bounded embedding norms), the sequence $\{\hat{\mathbf{z}}^{(t)}\}$ converges to a stationary point $\hat{\mathbf{z}}^*$ of $\mathcal{L}$. At stationarity, $\rho(t)$ converges to $\rho^*$ as defined in Eq. (10), since $\rho(t)$ is a continuous functional of the embedding distribution and the embeddings converge.

**(3) Empirical locality (conjecture).** Strictly speaking, parameter updates $\nabla_\theta \delta_{apn}$ computed on seen-class triplets affect $f_\theta$ globally (including its behavior on unseen-class inputs) since $f_\theta$ is a parametric MLP and is not locally supported on the input manifold. We therefore do not claim formal zero-gradient over unseen regions. Instead, we conjecture an *empirical* locality property: when (i) the residual structure with zero initialization keeps the cumulative perturbation magnitude bounded by the sum of training gradients, and (ii) gradient sparsity at convergence ($\rho^* \approx 3.5\%$ on FGVC-Aircraft) attenuates this sum, the resulting perturbation in unseen-class regions is small enough to preserve the pretrained semantic structure for retrieval purposes. This conjecture is empirically supported by the OOD Label Precision results in Section 4.2 and Figure 6, where EGA preserves or improves Label Precision on unseen categories while ICon and SRL, which lack the gradient sparsity property, collapse below the frozen baseline. A formal Lipschitz-based bound on this perturbation is left for future work.

**(4) Dependence on $m$.** The residual distance gap $\delta^*_{apn}$ at convergence is bounded by the within-class diameter $\Delta_c = \max_{x,x'\in c} d(\hat{\mathbf{z}}, \hat{\mathbf{z}}')$ for seen class $c$. For $m \leq \min_c \Delta_c$, the adapter can drive all within-class distances below the threshold, pushing $\rho^*$ toward zero. For $m > \min_c \Delta_c$, some triplets remain active at convergence because the within-class spread exceeds the margin, resulting in a strictly positive $\rho^*$. This explains the empirically observed increase in $\rho^*$ with larger $m$ reported in Table 4. □

# B Experimental Setup Details

**Backbones.** All experiments in the main paper use frozen CLIP ViT-B/32 [25] image embeddings as the base representation. To verify that EGA's benefits are not specific to this backbone, we further evaluate EGA on two stronger vision encoders: DINOv2-large [23] and SigLIP [39]. DINOv2-large is a self-supervised vision transformer trained on 142M images, while SigLIP is a supervised vision transformer trained on 400M image-text pairs. Both models produce higher-quality embeddings than CLIP ViT-B/32, as reflected in their stronger raw retrieval performance, and EGA continues to provide meaningful improvements on top of these stronger backbones, as shown in Table 5 in Section 4.4.

**Datasets.** We evaluate on four datasets covering both in-distribution and OOD retrieval scenarios. **CIFAR-100** (100 classes, 60K images) serves as the in-distribution benchmark: the adapter is trained and evaluated on the same class label space, with a 75/25 split between database and query sets. **CIFAR-10** (10 classes, 60K images) provides a cross-dataset OOD setting: the adapter is trained on CIFAR-100 and evaluated on the disjoint CIFAR-10 classes. **FGVC-Aircraft** (100 fine-grained aircraft variants, 10K images) and **Food-101** (101 food categories, 25K images for the test split we use) provide unseen-class OOD settings: classes are randomly partitioned into $80\%$ seen / $20\%$ unseen with a fixed seed, the adapter is trained on the seen split, and retrieval is evaluated strictly on the unseen split. Image embeddings for all datasets are extracted with frozen CLIP ViT-B/32.

**Baselines.** We compare EGA against the frozen CLIP baseline and four trained adapters, all sharing the same training data, evaluation protocol, and 75/25 retrieval split:

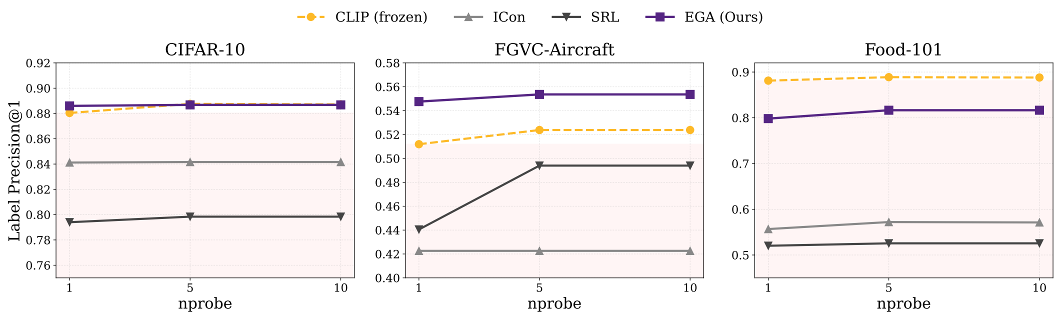

Figure 6: Label Precision@1 across three OOD benchmarks and three search budgets (nprobe $\in \{1, 5, 10\}$).

- **ICon** [1]: a global contrastive objective minimizing the KL divergence between the empirical similarity distribution and the class-membership distribution. We instantiate ICon on the same EGAMLP architecture used by our method ($\sim$4.2M parameters).
- **SRL** [4]: a structural regularization objective jointly optimizing batch-wide uniformity and within-class homogeneity, also instantiated on the EGAMLP architecture.
- **LoRA + InfoNCE** [10, 32]: a low-rank adapter (rank $r = 8$, $\alpha = 16$, $\sim$8K parameters) with zero-initialized residual structure, trained with supervised InfoNCE, which is a standard global contrastive loss.
- **LoRA + Triplet** [10]: identical low-rank architecture as above, but trained with the same small-margin ($m = 0.2$) triplet loss as EGA.

The two LoRA configurations isolate the effect of architectural capacity vs. loss function: comparing LoRA + InfoNCE against ICon/SRL holds the loss family roughly fixed while changing capacity, and comparing LoRA + Triplet against EGA holds the loss fixed while changing capacity.

**Indexing and metrics.** For all retrieval evaluations we use FAISS [16] `IndexIVFFlat` with nlist=10 centroids and report results at nprobe $\in \{1, 5, 10\}$. We measure both Label Precision (LP@$K$, Eq. 1) and ANNS Recall (AR@$K$, Eq. 2) at $K \in \{1, 3, 5, 10\}$.

**Training.** All adapters are trained for 150 epochs with AdamW (weight decay $10^{-4}$), cosine-annealed learning rate, and batch size 256. EGAMLP-based methods (EGA, ICon, SRL) use learning rate $10^{-4}$; LoRA variants use $10^{-3}$ to compensate for their smaller parameter count. Triplet-based methods sample one positive and one negative per anchor uniformly within each mini-batch; global contrastive methods (ICon, SRL, LoRA + InfoNCE) operate on the full pairwise similarity matrix. All experiments use a fixed random seed (42) for reproducibility.

**Compute platform.** All experiments were conducted on the Chameleon Cloud [17] platform using a compute node equipped with 256 AMD EPYC-7763 CPU cores, 512 GiB of RAM, and an NVIDIA A100 GPU of 80 GB HBM2e. The operating system is Ubuntu 24.04 LTS.

# C Additional Experimental Results

**Robustness across search budgets.** Figure 6 traces Label Precision@1 across three OOD benchmarks and three search budgets (nprobe $\in \{1, 5, 10\}$). The collapse pattern of ICon and SRL persists across all 18 measurement points (3 datasets $\times$ 3 budgets $\times$ 2 methods), ruling out the possibility that the degradation is an artifact of any particular benchmark or indexing configuration. EGA's relative ordering against other methods is also stable across budgets.
